

## HYDROTHERMAL ACTIVITY, METAMORPHISM, AND ORE DEPOSITS II

### SULFUR ISOTOPE FRACTIONATION IN LOW-TEMPERATURE SYSTEMS

At temperatures below about 400° C, sulfate ( $\text{SO}_4^{2-}$ ) species becomes the dominant form of oxidized sulfur, and the principal aqueous sulfur species in ore-forming fluids will be  $\text{H}_2\text{S}$ ,  $\text{HS}^-$ , and various sulfate species ( $\text{SO}_4^{2-}$ ,  $\text{HSO}_4^-$ ,  $\text{KSO}_4$ ,  $\text{NaSO}_4$ ,  $\text{CaSO}_4$  and  $\text{MgSO}_4$ ). Neglecting any fractionation between  $\text{H}_2\text{S}$  and  $\text{HS}^-$ , which will be small, the  $\delta^{34}\text{S}_{\text{H}_2\text{S}}$  of the fluid can be expressed as:

$$\delta^{34}\text{S}_{\text{H}_2\text{S}} = \delta^{34}\text{S}_{\text{fluid}} - \Delta_{\text{so}_4^{2-}} \times \left( \frac{R'}{R' + 1} \right) \quad 32.1$$

where  $R'$  is the molar ratio of sulfide to sulfate:

$$R' = \frac{\sum \text{SO}_4}{\sum \text{H}_2\text{S}} \quad 32.2$$

In general,  $R$  will be a function of  $f_{\text{O}_2}$ , pH, fluid composition and temperature. Figure 32.1 shows the difference between  $\delta^{34}\text{S}$  in sulfide and  $\delta^{34}\text{S}$  in the total fluid as a function of pH and  $f_{\text{O}_2}$ . Only under conditions of low pH and low  $f_{\text{O}_2}$ , will the  $\delta^{34}\text{S}$  of pyrite be the same as the  $\delta^{34}\text{S}$  from which it precipitated. For conditions of relatively high  $f_{\text{O}_2}$  or high pH, substantial differences between the  $\delta^{34}\text{S}$  of pyrite and the  $\delta^{34}\text{S}$  from which it precipitated are possible. Figure 32.2 shows the difference between  $\delta^{34}\text{S}$  in sulfide and  $\delta^{34}\text{S}$  in the total fluid as a function of the sulfate/sulfide ratio ( $R'$ ) and temperature. When the fluid is sulfide dominated, the  $\delta^{34}\text{S}$  of the sulfide and that of the bulk fluid will necessarily be nearly identical. For conditions where the concentrations of sulfate and sulfide are similar, large fractionations between sulfides and fluids from which they precipitate are possible.

At magmatic temperatures, reactions generally occur rapidly and most systems appear to be close to equilibrium. This will not necessarily be the case at lower temperatures because of the strong dependence of reaction rates on temperature. While isotopic equilibration between various sulfide species and between various sulfate species seems to be readily achieved at moderate and low temperatures, isotopic equilibration between sulfate and sulfide appears to be more difficult to achieve. Sulfate-sulfide reaction rates have been shown to depend on pH (reaction is

Figure 32.1. Difference in  $\delta^{34}\text{S}$  between  $\text{H}_2\text{S}$  and bulk fluid as a function of pH and  $f_{\text{O}_2}$  at 250°C. Equal concentration boundaries are shown for magnetite-hematite (M-H), magnetite-pyrite (M-Py), magnetite-pyrrhotite (M-Po), and pyrite-pyrrhotite (Py-Po). After Ohmoto and Rye (1979).

Figure 32.2. Difference in  $\delta^{34}\text{S}$  between  $\text{H}_2\text{S}$  and bulk fluid as a function of temperature and sulfate/sulfide ratio. Equal concentration boundaries pH neutral M: magnetite, H: hematite, Py: pyrite, Po: pyrrhotite, Bn: bornite, Cp: chalcopyrite. After Ohmoto and Rye (1979).

effects have also been observed in decomposition of sulfide minerals. Figure 32.3 illustrates some interesting possible effects that can arise as a result of disequilibrium.

If there is disequilibrium between sulfate and sulfide in solution, it is likely equilibrium will not be achieved between mineral pairs involving pyrite and chalcopyrite even when isotopic equilibrium is attained between other sulfides such as galena, sphalerite, and pyrrhotite. This is because precipitation of the former involves reactions such as:

whereas the latter involve only simple combinations, e.g.:

more rapid at low pH) and, in particular, on the presence of sulfur species of intermediate valences. Equilibration is much more rapid when such intermediate valence species are present. Presumably, this is because reaction rates between species of adjacent valance states (e.g., sulfate and sulfite) are rapid, but reaction rates between widely differing valance states (e.g., sulfate and sulfide) are much slower.

Low temperatures also lead to kinetic, rather than equilibrium, fractionations. As we saw, kinetic fractionation factors result from different isotopic reaction rates. Interestingly enough, the rates for oxidation of  $\text{H}_2^{32}\text{S}$  and  $\text{H}_2^{34}\text{S}$  appear to be nearly identical. This leads to the kinetic fractionation factor,  $\alpha_k$ , of  $1.000 \pm 0.003$ , whereas the equilibrium fractionation between  $\text{H}_2\text{S}$  and  $\text{SO}_4$  will be 1.025 at  $250^\circ\text{C}$  and 1.075 at  $25^\circ\text{C}$ . Thus sulfate produced by oxidation of sulfide can have  $\delta^{34}\text{S}$  identical to that of the original sulfide. Kinetic fractionations for the reverse reaction, namely reduction of sulfate, are generally larger. The fractionation observed is generally less than the equilibrium fractionation and depends on the overall rate of reduction: the fractionation approaches the equilibrium value when reaction rate is slow. Disequilibrium

Figure 32.3. Isotopic relationships between coexisting  $\text{H}_2\text{S}$  and  $\text{SO}_4^{2-}$  as a function of sulfate/sulfide ratio. (a) Equilibrium conditions at  $250^\circ\text{C}$  where  $\delta^{34}\text{S}_{\text{fluid}} = 0\text{‰}$ . (b) Non-equilibrium oxidation of  $\text{H}_2\text{S}$ . Isotopic composition of  $\text{H}_2\text{S}$  remains constant but that of sulfate changes due to addition of sulfate derived from non-equilibrium oxidation of  $\text{H}_2\text{S}$ . (c) Non-equilibrium mixing of  $\text{H}_2\text{S}$ -rich fluid A and  $\text{SO}_4$ -rich fluid B.  $\delta^{34}\text{S}_{\text{H}_2\text{S}}$  remains constant (equilibrium fractionation is achieved during reduction), but  $\delta^{34}\text{S}_{\text{SO}_4}$  varies due to addition of sulfate derived from oxidation of sulfide. After Ohmoto and Rye (1979).

32.4

### ISOTOPIC COMPOSITION OF SULFIDE ORES

A number of important sulfide deposits apparently were produced by reduction of sulfate ultimately derived from seawater. Their isotopic compositions are shown in Figure 32.4. The isotopic composition of these sulfides depends on the reduction mechanism, temperature, and whether the system was open or closed to sulfate and sulfide. At temperatures less than 50° C, the only mechanism for reduction of sulfate is bacterial. Optimal temperatures for such reduction are around 30 to 50° C. Deep euxinic basins such as the Black Sea are good examples of systems that are open to SO<sub>4</sub> but closed to H<sub>2</sub>S and where reduction is bacterial. In these cases, reduction occurs slowly at the bottom, but SO<sub>4</sub> is continuously supplied from the water mass. In such environments, sulfides appear to have a δ<sup>34</sup>S of 40 to 60‰ less than that of contemporaneous seawater (the sulfur isotopic composition of seawater has varied through time). A good example of such a deposit is the Kupferschiefer in Germany, where the most common δ<sup>34</sup>S is about -40‰, which is about 50‰ less than Permian seawater (+10‰).

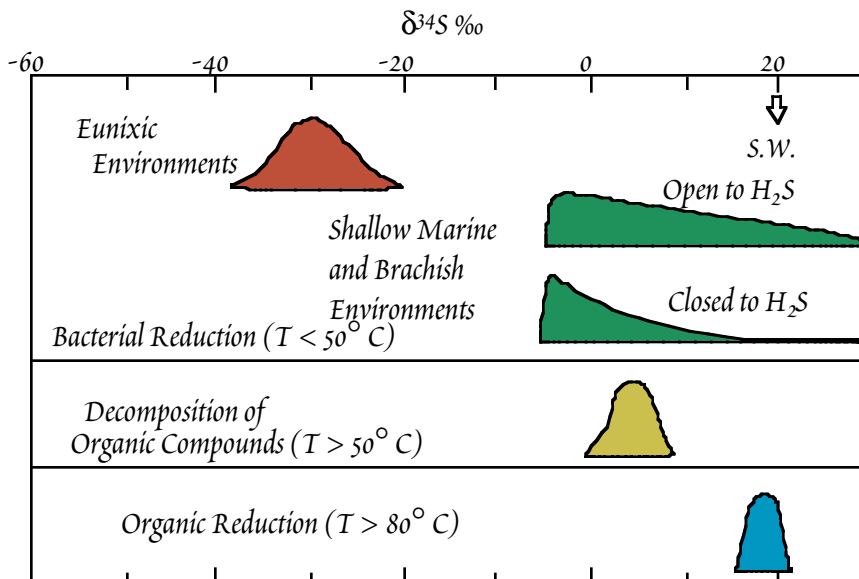

Figure 32.4. δ<sup>34</sup>S values observed sulfides produced in various low-temperature sulfate reducing environments. After Ohmoto and Rye (1969).

In systems closed to SO<sub>4</sub> but open to H<sub>2</sub>S, the process is similar to Rayleigh distillation. The composition of the sulfate, as a function of the fraction of sulfate remaining, *f*, is given by:

$$\delta^{34}\text{S}_{\text{SO}_4^{2-}} = \delta^{34}\text{S}_{\text{SO}_4^{2-}}^0 + 1000 (f^{1-\alpha} - 1) \quad 32.5$$

The composition of the sulfide at any time, *t*, is given by:

$$\delta^{34}\text{S}_{\text{H}_2\text{S}}^t = \delta^{34}\text{S}_{\text{SO}_4^{2-}}^t + 1000 (\alpha - 1) \quad 32.6$$

Systems closed to both species are analogous to equilibrium crystallization. In either case, the δ<sup>34</sup>S of both sulfide and sulfate increases during the reduction process. Systems closed to SO<sub>4</sub> characteristically show a spread in δ<sup>34</sup>S that is skewed toward positive values, have δ<sup>34</sup>S that increases in the later stages, and have both minimum and modal values that are approximately 25‰ lower than the original sulfate (e.g., contemporaneous seawater). Examples are the White Pine and Zambian copper deposits, which apparently formed in shallow marine or brackish environments.

At temperatures above 50° C, thermal decomposition of sulfur-bearing organic compounds produces H<sub>2</sub>S. The δ<sup>34</sup>S values of such H<sub>2</sub>S are typically 15‰ less than that of seawater. Such reduction is accelerated by the presence of S species of intermediate valence. The extent of isotopic fractionation in this process will depend on temperature.

In ridge crest hydrothermal systems, seawater sulfate is reduced by reactions with Fe<sup>2+</sup> such as:

Reduction most likely occurs at temperatures above 250° C (sulfide was not produced in basalt-seawater experiments below this temperature), and it is likely that equilibrium is achieved in this process. Modern seawater has a  $\delta^{34}\text{S}$  of +20, and values of  $\text{H}_2\text{S}$  between -5‰ and +20‰ (the latter value is a result of complete reduction of sulfate) are expected. Consistent with this prediction, sulfide in active seafloor hydrothermal vents has a  $\delta^{34}\text{S}$  of +3.5. This process produces the class of ores referred to either as stratabound sulfides or volcanogenic massive sulfides. Isotopic compositions of some example deposits are shown in Figure 32.5, along with the composition of contemporaneous seawater. They typically have  $\delta^{34}\text{S}$  approximately 17‰ lower than contemporaneous seawater.

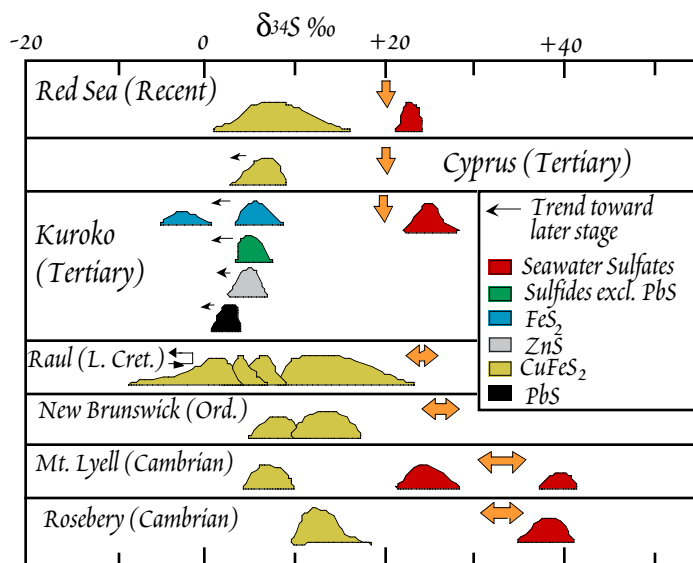

Figure 32.5.  $\delta^{34}\text{S}$  in volcanogenic massive sulfide deposits. Arrows show the isotopic composition of contemporaneous seawater sulfate. After Ohmoto and Rye (1979).

Figure 32.6.  $\delta^{34}\text{S}$  in porphyry copper sulfides and sulfates. After Ohmoto and Rye (1979).

The isotopic compositions of example porphyry copper deposits are shown in Figure 32.6. The sulfides in these generally have  $\delta^{34}\text{S}$  between -3 and +1‰, which is close to the mantle value, and the fractionation between sulfides and coexisting sulfates suggest equilibration temperatures between 450° C and 650° C, which is generally in good agreement with other temperature estimates. The isotopic compositions indicate the sulfur was derived from igneous sources, either as magmatic fluids or by dissolution of igneous sulfides. The low  $\delta^{34}\text{S}$  of Galore Creek suggests the oxidation state of the magma was high or that some sedimentary sulfide was incorporated. The high  $\delta^{34}\text{S}$  of Morococha suggests some sulfur was derived from the evaporites found in the surrounding country rock. H and O isotopic compositions in these deposits are generally inconsistent with magmatic derivation. It is possible these isotope ratios reflect overprint of meteoric water circulation after mineralization.

Mississippi Valley type deposits are carbonate-hosted lead and zinc sulfides formed under relatively low temperature conditions. Figure 32.7 shows the sulfur isotope ratios of some examples. They can be subdivided into Zn-rich and Pb-rich classes. The Pb-rich and most of the Zn rich deposits were formed between 70 and 120° C, while some of the Zn-rich deposits, such as those of the Upper Mississippi Valley, were formed at temperatures up to 200° C. Co-existing sulfides of the Pb-poor Upper Mississippi Valley deposits are in isotopic equilibrium whereas sulfur isotope equilibrium was most often not achieved in Pb-rich deposits. In the former,  $\delta^{34}\text{S}$  values are quite uniform over a large area, suggesting the ore-forming fluid supplied both metals

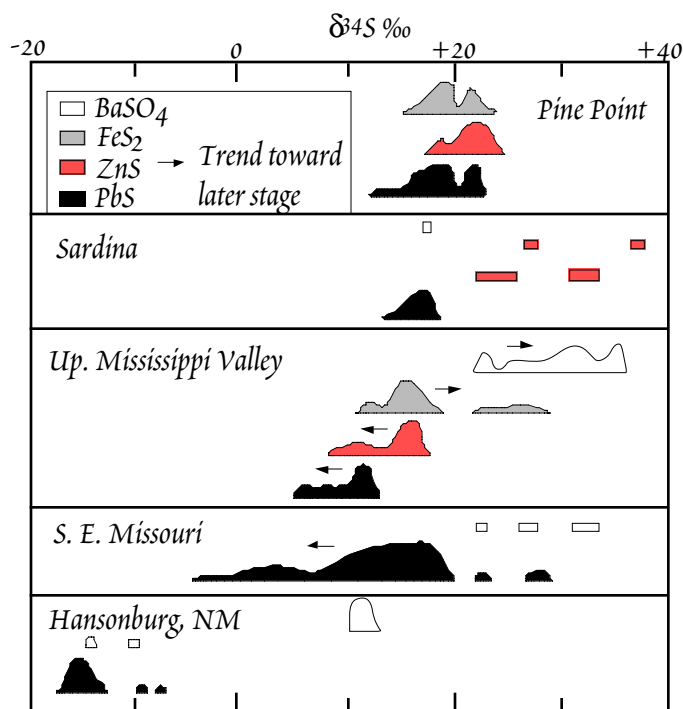

Figure 32.7. Sulfur isotope ratios in some Mississippi Valley-type Pb and Zn deposits. After Ohmoto and Rye (1979).

and sulfides and transported them over long distances. The high positive  $\delta^{34}\text{S}$  suggests the sulfur was ultimately derived from ancient seawater, perhaps from formation water or evaporites in deep sedimentary basins, and reduced by reaction with organic compounds.

$\delta^{34}\text{S}$  is correlated with Pb isotope ratios in galenas of the S. E. Missouri district. This, and the variability of  $\delta^{34}\text{S}$  suggests there was more than one source of the sulfur and lead. Isotopically heavy sulfur was apparently carried with the metal by the ore forming fluid while the isotopically heavy sulfur was derived from pyrite in the host rock. In Pine Point, sulfide may have been locally produced by reaction between sulfate-bearing fluids and organic matter in sediment. Local production of sulfide shortly before ore deposition may help to account for the lack of isotopic equilibrium in this deposit, since time is an element in the attainment of isotopic equilibrium.

Figure 32.8 illustrates a generalized model for the genesis of Mississippi Valley type deposits. In most instances, metals and sulfur appear to have been derived distant from sedimentary units, perhaps particularly from evaporites, by hot, deep-circulating meteoric water. In North America, most of these seem to have formed during or shortly after the late Paleozoic Appalachian-Ouchita-Marathon Orogeny. Mixing of the hot saline fluids with low salinity ground water was probably the immediate cause of metal precipitation in most instances. In others, such as Pine-Point, local reduction of sulfate in the fluids to sulfide may

have cause precipitation.
